Chambers of the Sheep Heart

The internal anatomy of the sheep heart is divided into four primary chambers: two atria and two ventricles. These chambers play crucial roles in receiving and pumping blood throughout the body. Understanding the structure and function of each chamber is vital when you label the internal anatomy of the sheep heart.

Right Atrium

The right atrium receives deoxygenated blood from the body via the superior and inferior vena cavae. It is located on the anterior side of the heart and serves as the initial chamber for systemic venous blood. The inner wall of the right atrium is relatively smooth except for the pectinate muscles, which help increase the atrial contraction force.

Right Ventricle

Blood from the right atrium flows into the right ventricle through the tricuspid valve. The right ventricle then pumps this deoxygenated blood into the pulmonary artery via the pulmonary valve. The walls of the right ventricle are thicker than the atria but thinner than the left ventricle, reflecting its role in pumping blood to the lungs.

Left Atrium

The left atrium receives oxygenated blood from the lungs through the pulmonary veins. This chamber is located posteriorly and has smoother internal walls compared to the right atrium. Blood from the left atrium passes through the mitral valve into the left ventricle.

Left Ventricle

The left ventricle is the thickest-walled chamber of the sheep heart due to its function of pumping oxygen-rich blood into the systemic circulation via the aorta. It generates high pressure to distribute blood efficiently throughout the body. The internal surface contains trabeculae carneae, which are muscular ridges that aid in ventricular contraction.

- Right Atrium: receives systemic deoxygenated blood
- Right Ventricle: pumps blood to lungs
- Left Atrium: receives oxygenated blood from lungs
- Left Ventricle: pumps blood to systemic circulation

Valves of the Sheep Heart

Valves in the sheep heart ensure unidirectional blood flow and prevent backflow between chambers and major vessels. When labeling the internal anatomy of the sheep heart, recognizing these valves is essential for understanding cardiac function.

Atrioventricular Valves

There are two atrioventricular (AV) valves: the tricuspid valve on the right side and the mitral valve on the left side. The tricuspid valve has three cusps and regulates blood flow from the right atrium to the right ventricle. The mitral valve, also called the bicuspid valve, has two cusps and controls flow from the left atrium to the left ventricle. Both valves are anchored by chordae tendineae to papillary muscles that prevent valve prolapse during ventricular contraction.

Semilunar Valves

The semilunar valves are located at the exits of the ventricles. The pulmonary valve controls blood flow from the right ventricle into the pulmonary artery, while the aortic valve regulates blood flow from the left ventricle into the aorta. These valves have three cusps each and open and close in response to pressure changes during the cardiac cycle.

- Tricuspid Valve: right atrium to right ventricle
- Mitral Valve: left atrium to left ventricle
- Pulmonary Valve: right ventricle to pulmonary artery
- Aortic Valve: left ventricle to aorta

Major Blood Vessels

When labeling the internal anatomy of the sheep heart, identifying the major blood vessels connected to the heart is critical. These vessels facilitate the inflow and outflow of blood, maintaining systemic and pulmonary circulation.

Vena Cavae

The superior and inferior vena cavae are large veins that return deoxygenated blood from the body to the right atrium. The superior vena cava brings blood from the upper body, whereas the inferior vena cava drains blood from the lower body regions.

Pulmonary Artery

The pulmonary artery carries deoxygenated blood from the right ventricle to the lungs for oxygenation. It bifurcates into left and right branches, directing blood to each lung.

Pulmonary Veins

The pulmonary veins return oxygenated blood from the lungs to the left atrium. Typically, there are four pulmonary veins, two from each lung, that enter the left atrium.

Aorta

The aorta is the largest artery in the body and carries oxygen-rich blood from the left ventricle to systemic circulation. It arches upward and branches into major arteries supplying the head, arms, and lower body.

- Superior Vena Cava: drains upper body
- Inferior Vena Cava: drains lower body
- Pulmonary Artery: carries blood to lungs
- Pulmonary Veins: return blood from lungs
- Aorta: distributes oxygenated blood systemically

Conduction System of the Sheep Heart

The conduction system controls the heartbeat by generating and transmitting electrical impulses that stimulate heart muscle contraction. Proper labeling of the internal anatomy of the sheep heart includes identifying these specialized structures.

Sinoatrial (SA) Node

The SA node, located in the right atrium near the superior vena cava opening, is the heart's natural pacemaker. It initiates electrical impulses that set the rhythm for the entire heart.

Atrioventricular (AV) Node

Situated at the junction between the atria and ventricles near the septum, the AV node delays the electrical signal to allow atrial contraction before ventricular contraction begins.

Bundle of His and Purkinje Fibers

The Bundle of His transmits impulses from the AV node through the interventricular septum, branching into right and left bundle branches. These branches further subdivide into Purkinje fibers that spread the impulse throughout the ventricles, facilitating coordinated contraction.

- SA Node: initiates heartbeat
- AV Node: delays impulse transmission
- Bundle of His: conducts impulses to ventricles
- Purkinje Fibers: distribute impulses in ventricles

Techniques to Label the Internal Anatomy

Accurate labeling of the internal anatomy of the sheep heart requires systematic dissection and visualization techniques. These methods enable clear identification of structures for educational and clinical purposes.

Dissection and Exposure

Begin by making a precise incision along the heart's external surface to expose the internal chambers. Careful dissection allows visualization of the atria, ventricles, valves, and vessels without damaging delicate tissues.

Use of Anatomical Markers

Applying color-coded labels or pins to specific structures can aid in distinguishing between different parts. For example, red markers may denote oxygenated blood pathways, while blue markers indicate deoxygenated areas.

Diagrammatic Representation

Creating detailed anatomical diagrams or using labeled charts alongside the actual heart specimen helps reinforce learning and accurate identification of structures. Combining visual aids with physical labeling enhances comprehension.

- Careful dissection to preserve internal structures
- Color-coded markers for differentiation
- Use of anatomical diagrams for reference
